HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

A Proposal to Search for Transparent Hidden Matter Using Optical Scintillation

M. Moniez

Laboratoire de l'Accélérateur Linéaire, IN2P3-CNRS, Université de Paris-Sud, B.P. 34, 91898 Orsay Cedex, France

It is proposed to search for scintillation of extragalactic sources through the last unknown baryonic structures. Appropriate observation of the scintillation process described here should allow one to detect column density stochastic variations in cool Galactic molecular clouds of order of $\sim 3 \times 10^{-5} \text{ g/cm}^2$ – that is $10^{19} \text{ molecules/cm}^2$ – per $\sim 10\,000 \text{ km}$ transverse distance.

1 Introduction

It has been suggested that a hierarchical structure of cold H_2 could fill the Galactic thick disk¹ or halo², providing a solution for the Galactic dark matter problem. This gas could form undetectable “clumpuscles” of 10 AU size at the smallest scale, with a column density of $10^{24-25} \text{ cm}^{-2}$, and a surface filling factor less than 1%. Light propagation is delayed through such a structure and the *average* transverse gradient of optical path variations is of order of 1λ per 10 000 km at $\lambda = 500 \text{ nm}$. These H_2 clouds could then be detected through their diffraction and refraction effects on the propagation of the light of background stars (for a more detailed paper on this proposal see (³)).

2 Detection mode of extended H_2 clouds: principle

Due to index refraction effects, an inhomogeneous transparent medium (hereafter called screen) distorts the wave-fronts of incident electromagnetic waves (see Fig. 2). The extra optical path induced by a screen at distance z_0 can be described by a phase delay $\delta(x_1, y_1)$ in the plane transverse to the observer-source line. The amplitude A_0 in the observer’s plane results from the subsequent propagation, that is described by the Huygens-Fresnel diffraction theory

$$A_0(x_0, y_0) = \frac{Ae^{2i\pi z_0/\lambda}}{2i\pi R_F^2} \iint_{-\infty}^{+\infty} e^{\frac{2i\pi\delta(x_1, y_1)}{\lambda}} e^{i\frac{(x_0-x_1)^2+(y_0-y_1)^2}{2R_F^2}} dx_1 dy_1, \quad (1)$$

where A is the incident amplitude (before the screen), taken as a constant for a very distant on-axis source, and $R_F = \sqrt{\lambda z_0/2\pi}$ is the Fresnel radius. R_F is of order of 1500 km to 15 000 km at $\lambda = 500 \text{ nm}$, for a screen distance z_0 between 1 kpc to 100 kpc. The resulting intensity in the observer’s plane is affected by strong interferences (the so-called speckle) if $\delta(x_1, y_1)$ varies stochastically of order of λ within the Fresnel radius domain. This is precisely the same order of magnitude as the average gradient that characterizes the hypothetic H_2 structures.

As for radio-astronomy^{4,5}, the stochastic variations of $\delta(x_1, y_1)$ can be characterized by the diffractive length scale R_{diff} , defined as the transverse separation for which the root mean square of the optical path difference is $\lambda/2\pi$.

- If $R_{diff} \gg R_F$, the screen is weakly diffusive. The wavefront is weakly corrugated, producing weakly contrasted patterns with length scale R_F in the observer’s plane (Fig. 2).

Figure 1: Relative intensity diffraction patterns produced in the observer's plane, perpendicularly to a width step or prism. From left to right: - Step of optical path $\delta = \lambda/4$ - Prism of optical path with $\delta = X_0 \times \lambda/2$ for $X_0 > 0$. - Step of optical path $\delta = \lambda/2$, for extended disk-sources of reduced radius $R_S = 1, 2$ and 4 . The X_0 - axis origin ($X_0 = x_0/\sqrt{\pi}R_F$) is the intercept of the source-step line with the observer's plane.

Figure 2: The two scintillation regimes: Left: $R_{diff} \gg R_F$. The weakly distorted wavefront produces a weak scintillation at scale R_F in the observer's plane. Right: $R_{diff} \ll R_F$. The strongly distorted wavefront produces strong scintillation at scales R_{diff} (diffractive mode) and R_{ref} (refractive mode).

- If $R_{diff} \ll R_F$, the screen is strongly diffusive. Two modes occur, the diffractive scintillation – producing strongly contrasted patterns characterized by the length scale R_{diff} – and the refractive scintillation – giving less contrasted patterns and characterized by the large scale structures of the screen R_{ref} –.

We focus here on the strong diffractive mode, which should produce the most contrasted patterns and is easily predictable.

3 Basic configurations

Fig. 1 (left) displays the expected intensity variations in the observer's plane for a point-like monochromatic source observed through a transparent screen with a step of optical path $\delta = \lambda/4$ and through a prism edge. The inter-fringe is – in a natural way – close to the length scale defined by $\sqrt{\pi}R_F$.

Such configurations model the edge of a H_2 structure, because they have the same average gradient of optical path. More generally, contrasted patterns take place as soon as the second derivative of the optical path is different from zero.

4 Limitations from spatial and temporal coherences

At optical wavelengths, diffraction pattern contrast is severely limited by the size of the source r_S . Fig. 1 (right) shows the diffraction patterns for different reduced source radii, defined as $R_S = r_S/(\sqrt{\pi}R_F) \times z_0/z_1$, where z_1 is the distance from the source to the screen.

Table 1: Configurations leading to strong diffractive scintillation. Here we assume a regime characterized by $R_{diff} \leq R_F$, or at least a transitory regime as described in Section 3 – characterized by $R_F -$, for example if an inhomogeneity due to a turbulent mechanism crosses the line of sight. Numbers are given for $\lambda = 500$ nm.

		SCREEN					
		atmos- phere	solar system	solar suburbs	Galactic		
Distance		10 km	1 AU	10 pc	300 pc	1 kpc	10 kpc
R_F to \times by $\left[\frac{\lambda}{500 \text{ nm}}\right]^{\frac{1}{2}}$		2.8 cm	109 m	157 km	860 km	1570 km	5000 km
Transverse speed V_T		1 m/s	10 km/s	20 km/s	30 km/s	40 km/s	200 km/s
t_{scint} to \times $\left[\frac{\lambda}{500 \text{ nm}}\right]^{\frac{1}{2}} \left[\frac{R_{diff}}{R_F}\right]$		0.03 s	0.01 s	8 s	29 s	40 s	25 s
m_{scint} in % to multiply by $\left[\frac{\lambda}{500 \text{ nm}}\right]^{\frac{1}{2}} \left[\frac{R_{diff}}{R_F}\right] \left[\frac{r_S}{r_\odot}\right]^{-1}$		100%	32% \times $\left[\frac{d}{10 \text{ pc}}\right]$	2.2% \times $\left[\frac{d}{1 \text{ kpc}}\right]$	4.1% \times $\left[\frac{d}{10 \text{ kpc}}\right]$	2.2% \times $\left[\frac{d}{10 \text{ kpc}}\right]$	7.1% \times $\left[\frac{d}{100 \text{ kpc}}\right]$
SOURCE		DIFFRACTIVE MODULATION INDEX m_{scint} (to multiply by $\sqrt{\lambda/500 \text{ nm}} \times R_{diff}/R_F$)					
Location	Type						
nearby 10pc	any star	$\ll 1\%$	$< 100\%$				
Galactic 8kpc	star	in a	100%	1-70%	1-10%		
LMC 55kpc	A5V ($r_S = 1.7r_\odot$)	tele-	100%	70%	13%	7%	2%
M31 725kpc	B0V ($r_S = 7.4r_\odot$)	sco-	100%	100%	40%	22%	7%
z=0.2–0.9Gpc	SN Ia	> 1 m	100%	70%	13%	7%	2%
z=1.7–1.7Gpc	Q2237+0305		100%	> 45%	> 8%	> 4%	> 1.4%

In return, temporal coherence with the standard UBVRI filters is sufficiently high to enable the formation of contrasted interferences in the configurations considered here. The fringe jamming induced by the wavelength dispersion is also much smaller than the jamming due to the source extension.

5 What is to see?

An interference pattern with inter-fringe of $\sim R_F$ (1000 – 10 000 km at $\lambda = 500$ nm) is expected to sweep across the Earth when the line of sight of a sufficiently small astrophysical source crosses an inhomogeneous transparent Galactic structure (see Table 1). This pattern moves at the transverse velocity V_T of the diffusive screen. Its shape may also evolve, due to random turbulence in the scattering medium. For the Galactic H_2 clouds we are interested in, we expect a typical modulation index m_{scint} (or contrast) ranging between 1% and $\sim 20\%$, critically depending on the source apparent size. The time scale $t_{scint} = R_F/V_T$ of the intensity variations is of order of 30 s. As the inter-fringe scales with $\sqrt{\lambda}$, one expects a significant difference in the time scale t_{scint} between the red side of the optical spectrum and the blue side. This property might be used to sign the diffraction phenomenon at the R_F natural scale.

6 How to see it?

Minimal hardware: from Table 1, we deduce that the minimal magnitude of extragalactic stars that are likely to undergo a few percent modulation index from a Galactic molecular cloud is $M_V \sim 20.5$ (A5V star in LMC or B0V in M31). Therefore, the search for diffractive scintillation needs the capability to sample every ~ 10 s (or faster) the luminosity of stars with $M_V > 20.5$, with a point-to-point precision better than a few percent. This performance can be achieved using a 2 meter telescope with a high quantum efficiency detector allowing a negligible dead time between exposures (like frame-transfer CCDs). Multi-wavelength detection capability is highly desirable to exploit the dependence of the diffractive scintillation pattern with the wavelength.

Chances to see something? The 1% surface filling factor predicted for gaseous structures is also the maximum optical depth for *all* the possible refractive (weak or strong) and diffractive scintillation regimes. Under the pessimistic hypothesis that strong diffractive regime occurs only when a Galactic structure enters or leaves the line of sight, the duration for this regime is of order of ~ 5 minutes (time to cross a few fringes) over a total typical crossing time of ~ 400 days. Then the diffractive regime optical depth τ_{scint} should be at least of order of 10^{-7} and the average exposure needed to observe one event of ~ 5 minute duration is $10^6 \text{ star} \times \text{hr}^a$. It follows that a wide field detector is necessary to monitor a large number of stars.

7 Foreground effects, background to the signal

Atmospheric effects: Surprisingly, atmospheric intensity scintillation is negligible through a large telescope ($m_{scint} \ll 1\%$ for a > 1 m diameter telescope⁶). Any other long time scale atmospheric effect such as absorption variations at the sub-minute scale (due to fast cirruses for example) should be easy to recognize as long as nearby stars are monitored together.

The solar neighbourhood: Overdensities at 10 pc could produce a signal very similar to one expected from the Galactic clouds. But in this case, even big stars should undergo a contrasted diffractive scintillation; the distinctive feature of scintillation through more distant screens (> 300 pc) is that *only the smallest stars* are expected to scintillate. It follows that simultaneous monitoring of various types of stars at various distances should allow one to discriminate effects due to solar neighbourhood gas and due to more distant gaseous structures.

Sources of background? Physical processes such as asteroseismology, granularity of the stellar surface, spots or eruptions produce variations of very different amplitudes and time scales. A few categories of recurrent variable stars exhibit important emission variations at the minute time scale⁷, but their types are easy to identify from spectrum.

8 Conclusions and perspectives

Structuration of matter is perceptible at all scales, and the eventuality of stochastic fluctuations producing diffractive scintillation is not rejected by observations. In this paper, I showed that there is an observational opportunity resulting from the subtle compromise between the arm-lever of interference patterns due to hypothetic diffusive objects in the Milky-Way and the size of the extra-galactic stars. The hardware and software techniques required for scintillation searches are currently available. Tests are under way to validate some of the ideas discussed here.

If some indications are discovered with a single telescope, one will have to consider a project involving a 2D array of telescopes, a few hundred and/or thousand kilometers apart. Such a setup would allow to temporally and spatially sample an interference pattern, unambiguously providing the diffraction length scale R_{diff} , the speed and the dynamics of the scattering medium.
